**Evaluation of antihypertensive therapy in diabetic hypertensive patients: impact of ischemic heart disease**

**ABSTRACT**

Macrovacular complications are common in diabetic hypertensive patients. Appropriate antihypertensive therapy and tight blood pressure control are believed to prevent or delay such complication.

Objective: To evaluate utilization patterns of antihypertensive agents and blood pressure (BP) control among diabetic hypertensive patients with and without ischemic heart disease (IHD).

Methods: Retrospective cohort study of all diabetic hypertensive patients attending Al-watani medical center from August 2006 until August 2007.

Results: 255 patients were included in the study; their mean age was 64.4 (SD=11.4) years. Sixty one (23.9%) of the included patients was on target BP. Over 60% of the total patients were receiving angiotensin-converting enzyme inhibitors (ACEI)/angiotensin receptor blocker (ARB), followed by diuretics (40.8%), calcium channel blockers (25.1%) and beta-blockers (12.5%). The majority (> 55%) of patients were either on mono or no drug therapy. More than 55% of patients with controlled BP were using ACE-I. More than half (50.8%) of the patients with controlled BP were on combination therapy while 42.3% of patients with uncontrolled BP were on combination therapy (p=0.24). More patient in the IHD achieved target BP than those in non-IHD group (p=0.019). Comparison between IHD and non-IHD groups indicated no significant difference in the utilization of any drug class with ACE-I being the most commonly utilized in both groups.

Conclusions: Patterns of antihypertensive therapy were generally but not adequately consistent with international guidelines. Areas of improvement include increasing ACE-I drug combinations, decreasing the number of untreated patients, and increasing the proportion of patients with controlled BP in this population.

**RESUMEN**

Las complicaciones macrovasculares son frecuentes en pacientes diabéticos hipertensos. Se cree que un apropiado tratamiento antihipertensivo y un control estrecho de la presión arterial previenen o retrasan estas complicaciones.

Objetivo: Evaluar los patrones de utilización de antihipertensivos y el control de la presión arterial (PA) en pacientes diabéticos hipertensos con y sin enfermedad isquémica cardiaca (EIC).

Métodos: Estudio de cohorte retrospectivo de todos los pacientes diabéticos hipertensos que acudieron al centro médico Al-watani desde agosto 2006 a agosto 2007. Se compararon las proporciones de pacientes que recibían 1, 2, 3 o 4 o más medicamentos, y por separado los pacientes con y sin EIC. El control de presión arterial (menor o igual a 130/80 mmHg) se comparó en los pacientes recibiendo ningún tratamiento, monoterapia o tratamiento de combinación y por separado los que tenían o no EIC.

Resultados: Se incluyeron en el estudio 255 pacientes; su media de edad era de 64,4 (DE=11,4) años. Sesenta y uno (23,9%) de los pacientes incluidos estaban en la presión arterial deseada. Más del 60% del total recibían inhibidores de la enzima convertidora de la angiotensina (IECA)/Antagonistas del receptor de angiotensina (ARA), seguidos de diuréticos (40,8%), bloqueantes de canales de calcio (25,1%), y beta-bloqueantes (12,5%). La mayoría (más del 55%) estaban en monoterapia o sin tratamiento. Más del...
There are a growing number of pharmacological treatment options for patients with hypertension. However, the choice of antihypertensive drug class is influenced by many factors such as the presence of co-morbid conditions. The seventh report of the Joint National Committee on the Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC) stated that angiotensin converting enzyme inhibitors (ACE-I) is an important component of most regimens to control BP in diabetic patients. In those patients, ACE-I may be used alone, but much more effective when combined with thiazide-type diuretic or other antihypertensive drugs. The JNC 7th report recommended that BP in diabetics be controlled to levels of 130/80 mm Hg or lower. Rigorous control of BP is paramount for reducing the progression of diabetic nephropathy to end stage renal disease (ESRD). In hypertensive patients with ischemic heart disease (IHD), the JNC 7th report recommended the use of beta blockers (BB) unless contraindicated. If BB therapy was inadequate or contraindicated, either long acting dihydropyridine or nondihydropyridine-type calcium channel blockers (CCB) may be used.

The primary objectives of this project were (1) to evaluate and compare utilization of antihypertensive therapies according to JNC 7th report for diabetic patients with and without IHD, and (2) to assess BP control among diabetic hypertensive patients.

METHODS

Settings and Study Design

This is an observational retrospective study conducted at Al-Watani governmental hospital and medical center, the largest non-surgical medical center in north Palestine with in and out-patient community medical services. Practitioners at this center were a combination of specialized and general physicians.

Participants and Data Collection

Data were collected for the period of August 1, 2006 to August 1, 2007. All inpatients as well as all outpatients from clinics were screened. We used the medical records of the patients to obtain diagnostic information, demographic information, laboratory test results, vital signs, and prescription drug use. All aspects of the study protocol, including access to and use of the patient clinical information, were authorized by the medical ethics committee and the local health authorities. All diabetic hypertensive patients seen during the study period were investigated.

History of Ischemic heart disease was obtained from patients’ medical files. Patients with history of angina pectoris or myocardial infarction or any diagnosis of coronary artery disease were considered to have IHD. Reduced renal function or renal impairment was defined as creatinine clearance (CrCl) ≤ 60 ml/min. This cut off point was used by JNC 7th report to guide therapy for patients with chronic kidney disease (CKD). Creatinine clearance was calculated using Cockcroft-Gault.
**Statistical Analysis**

Chi square test was used to test significance between categorical variables while the independent samples t-test was used to test for significance between continuous variables. Data were expressed as mean (standard deviation) for continuous variables and as frequency for categorical variables.

**RESULTS**

During the study period, 334 consecutive diabetic hypertensive patients were identified. Eighty five patients were excluded because they have CHF and/or ESRD. The 255 who met the inclusion criteria were 110 (43.1%) males and 145 (56.9%) females. The mean age of the included patients was 64.58 (SD=11.40) years. The most recently recorded values of systolic, diastolic BP and random blood glucose level were 151.17 (SD=29.40); 86.22 (SD=13.06) mmHg and 257.82 (SD=131.14) mg/dl respectively. The mean CrCl of the patients was 100.24 (SD=73.1) mL/min with 79 patients had reduced renal function (CrCl<60 mL/min). The average number of chronic diseases present among the study patients was 2.83 (SD=0.7). The recommended target BP of equal or lower 130/80 mmHg was achieved in only 61 (23.9%) patients. A total of 109 (42.7%) patients (group I) were having history of IHD while 146 (57.3%) were not (group II). Table 1 shows the clinical and demographic characteristics of the study population and compares these characteristics between patients with and without IHD. No significant difference in the average number of antihypertensive medication was found between patients with and without IHD was found (1.5 SD=0.3 versus 1.4 SD=0.8, p=0.29). However, significantly (p=0.019) more patients with IHD (31.2%) were on target BP than patients without IHD (18.5%).

n= total number of patients.

ACEIs/ ARB = angiotensin converting enzyme inhibitor/ angiotensin receptor blocker. BB = β-blocker, CCB = calcium channel blocker.

*Total exceeds 100% because data are overlapping due to multiple use of medication.
Of the study patients, 228 (89.4%) were treated with antihypertensive drugs, whereas 27 (10.6%) were solely on non-pharmacological interventions. Mono-therapy was prescribed for 115 (45.09%), and were solely on non-pharmacological interventions. With antihypertensive drugs, whereas 27 (10.6%) patients in 2 (1.7%) patients (Table 2). A total of 363 antihypertensive medications were prescribed for the 255 patients. The average number of antihypertensive medications prescribed for the patients was 1.42 (SD=0.8) (range: 0 to 4) and was positively correlated with the duration of DM (p<0.001), duration of HTN (p=0.049), and number of chronic diseases (p<0.0001) but not with age (p=0.16). More than half (50.8%) of the patients with controlled BP and 42.3% of the patients with uncontrolled BP were using combination therapy; this difference, however, was insignificant (p=0.3), (Figure 1). Distribution of patients based on BP control and number of antihypertensive medication utilized is shown in Figure 2.

![Figure 1: Distribution of blood pressure (BP) control based on the number of anti-hypertensive medications used](image)

The most commonly antihypertensive drug classes utilized by the patients were ACE-I (157, 43%) followed by diuretics (104, 28.7%) and CCB (64, 17.6%). Overall utilization of antihypertensive drug classes is shown in Table 2. Monotherapy was the most common mode of therapy among the patients (115, 45.09%). ACE-I was used as a monotherapy in 69 (60%), diuretics in 27 (23.4%), CCB in 10 (8.7%) and BB in 9 (7.6%) patients. The two-drug combination regimen was prescribed to 93 patients. The most common 2-drug combination was “ACE-I with others” which was utilized by 70 (75.26%) patients. Overall, more than half of the patients with controlled BP were on ACE-I and/or diuretics (Table 2).

Antihypertensive pattern and medications prescribed for patients with or without IHD were investigated. Patients with IHD were prescribed a total of 162 antihypertensive medications, an average of 1.49 (SD=0.83) medications per patient. A total of 11 (10.1%) patients were on non-pharmacologic therapy, 45 (41.3%) on monotherapy and 53 (48.6%) were on combination therapy. ACE-I was the most commonly (22.9%) prescribed drug class as monotherapy in this group of patients. ACE-I was the most commonly (62.5%) prescribed drug in combination therapy in group (I) patients. A total of 201 antihypertensive medications were prescribed to patients without IHD, an average of 1.41 (SD=0.78) per patient. A total of 16 (11%) patients were on non pharmacological therapy, 70 (47.9%) on mono therapy and 60 (41.1%) patients were on combo therapy. ACE-I (30.1%) were the most commonly prescribed monotherapy drug for patients in group (II). ACE-I was the most commonly (63.2%) prescribed drug in combination therapy in patients without IHD. There was no significant difference in the overall utilization of any drug class and patients in either group (Table 3).

**DISCUSSION**

We evaluated the patterns of antihypertensive drug therapy in diabetic hypertensive patients with and without IHD. Our study revealed that more than half (55%) of the total patients were on single or no antihypertensive therapy and that less than one third of the patients were on target BP. This study also showed that more than one third of the total patients had IHD suggesting that screening and preventive therapies for coronary artery diseases among diabetic hypertensive patients are important to decrease morbidity and mortality among this category of patients. This study also showed that the majority of patients were receiving ACE-I and/or diuretics with CCB and BB being lesser commonly used. These findings indicate that medication use was mostly consistent with JNC 7th report recommendation among diabetic hypertensive patients. However, there is still room for improvement with regard of combination therapy and better BP control. We expected that patients with IHD will be using more CCB and/or BB than patients without IHD. However, there was no significant difference in the use of CCB and BB in the groups and that ACE-I and/or diuretics were the
ACE-I was the most commonly prescribed drug class both in mono and combination therapy. The use of ACE-I among diabetic hypertensive patients is in accordance with the JNC recommendations for the management of hypertension among diabetic hypertensive patients. The reported mono and combination use of ACE-I was 43.3% which is closer to that reported from Bahrain but less than that reported from USA in treating diabetic hypertensive patients. The results obtained in the current study were different from those reported in a study carried out five years ago in Palestine. In the current study, there was an overall increase in the use of ACE-I compared to that reported five years ago.

In a previous study carried out on patients with diabetes and hypertension, the reported prevalence of cough associated with the use of ACE-I was 14.9%, with 4.7% of patients interrupting treatment as a result. Similarly, the UKPDS Group noted that 4% of patients receiving captopril discontinued treatment due to cough. These reported adverse effects of ACE-I could partially explain the underutilization of ACE-I reported in the current study. ARBs are considered appropriate agents if patients cannot tolerate an ACE-I. However, the use of ARBs were rarely prescribed in the current study.

Diuretics ranked second when considering overall utilization of antihypertensive drugs and second when considering antihypertensive monotherapy. Combination of ACE-I with diuretic was the most commonly prescribed. This combination is pharmacologically favorable since it produces an additive antihypertensive effect and minimizes most adverse effects of either the ACE-I or the diuretics especially hypokalemia. The importance of the diuretic agent was emphasized by the “Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial” ALLHAT study. Calcium channel blockers (CCB) ranked third in monotherapy and ranked third in overall antihypertensive drug utilization. The non-dihydropyridine, diltiazem, was the most commonly prescribed CCB and verapamil being the least commonly prescribed. The dihydropyridine, nifedipine and amlodipine, were in between. The popularity of the non-DHP diltiazem may be due to its reported positive effects on diabetic proteinuria. ACE-I plus CCB combination was not very common, although it could provide synergistic antihypertensive and renoprotective activity, but their effects on proteinuria is comparable to ACE-I alone. Non-DHP (e.g. diltiazem) plus ACE-I combination has been reported to lower insulin resistance and has an additive anti-proteinuric effect.

Similar studies conducted by a research group in Bahrain on patients with type 2 diabetes mellitus and hypertension showed that the prescribing of antihypertensive medications differ in many instances from the world health organization guidelines especially regarding the choices and drug combinations of antihypertensive drugs and that the appropriateness of anti-diabetic drug choice is questionable in relation to the antihypertensive drug used. A second study carried out in Bahrain by the same group mentioned above compared family physicians’ and general practitioners’ approaches to drug management of diabetic hypertension. In this study, the authors carried out a retrospective prescription-based study on 1266 diabetic hypertensive patients. The authors concluded that there are substantial differences between Family physicians and general practitioners in terms of preference for different drug classes for the management of diabetic hypertension and that there was suboptimal compliance among both FP and GP to international recommendations. Finally, it is interesting to note that the extent of BP control achieved in groups treated with mono-therapy or combination therapy did not differ significantly. Similar findings were obtained by Sequeira and co-workers and Westheim and co-workers. Potential explanation for the high proportions of poor BP control could be the lack of drug compliance among diabetic patients as a result of adverse events of the antihypertensive medications.

From the current study, we recommend (1) better drug education for health care providers regarding appropriate and international guidelines for diabetic hypertensive patients, and (2) better follow up for
their BP control. This could be achieved through clinical pharmacist whose responsibility is to deliver continuing medical education in the field of current pharmacotherapy.

CONCLUSIONS

We concluded from this study that there was a suboptimum use of combination therapy among diabetic hypertensive patients in general. Furthermore, the majority of patients were not on target blood pressure. Patterns of antihypertensive therapy were generally but not adequately consistent with international guidelines. Areas of improvement include increasing ACE-I drug combinations, decreasing the number of untreated patients, and increasing the proportion of patients with controlled blood pressure in this population.
